```
$i = 1;
while($i < 10) {
    if ($i % 2 == 0) {
        print "{$i} is even" . PHP_EOL;
    }
    $i++;
}
print "All done.";
```

```
Output:
2 is even
4 is even
6 is even
8 is even
All done.
```

This simple example initializes `$i = 1;` and increments it by *1* on each iteration of the loop. Before each iteration executes, the expression `$i < 10` is evaluated, so once the variable's value reaches *10*, the expression is `false`, and this causes the loop to terminate, and program control flows to the next statement. Of course, if the expression is always `true`, the loop will run forever (or at least until interrupted by some other means), for example:

```
$cliIn = fopen("php://stdin", "r");
while (true) {
    print "Enter 'stop' to terminate" . PHP_EOL;
    $input = fgets($cliIn);
    if (strpos($input, 'stop') !== false) {
        break;
    }
    print "You entered {$input}" . PHP_EOL;
}
fclose($cliIn);
print "Terminating.";
```
