There's just one small problem: the data stored for sales has a different model to that for repairs. In fact, the only common property between the two is the car registration number (or index if you prefer). Let's further complicate matters by having our data sources as multidimensional arrays. The internal comparison function used by `array_diff()` and `array_intersect()` isn't going to work for us here, it's only intended for comparing scalars (and will emit various errors if used with composite type elements). Instead, we're going to write a small function that just tests a small part of each element's data and use it as a callback to `array_uintersect()`:

```
$advertised = [
    [
        'registration' => 'AAA 1A',
        'model' => 'Ford Prefect'
    ],
    [
        'registration' => 'BBB 1B',
        'model' => 'Vauxhall Viva'
    ],
];

$outForRepair = [
    [
        'registration' => 'AAA 1A',
        'fault' => 'Missing towel',
    ]
];

$deListUntilRepaired = array_uintersect($advertised, $outForRepair,
function ($ads, $reps) {
    return $ads['registration'] <=> $reps['registration'];
});

print_r($deListUntilRepaired);
```
