We have `php74` and `php84` available from the command line, but not `php`. A simple symlink will suffice if that's a necessity for you:

```
$ sudo ln -s /usr/bin/php84 /usr/bin/php
$ php -v
PHP 8.4.12 (cli) (built: Aug 26 2025 13:36:28) (NTS gcc x86_64)
Copyright (c) The PHP Group
Built by Remi's RPM repository <https://rpms.remirepo.net/>
#StandWithUkraine
Zend Engine v4.4.12, Copyright (c) Zend Technologies
    with Zend OPcache v8.4.12, Copyright (c), by Zend Technologies
```

With Homebrew

As previously mentioned, macOS does not have a native CLI package manager, but the excellent Homebrew system fills the gap. To install Homebrew on your macOS simply run the following command:

```
/bin/bash -c "$(curl -fsSL https://raw.githubusercontent.com/Homebrew/
install/HEAD/install.sh)"
```

Homebrew installation might also trigger an install of XCode Command Line Tools (XCode is Apple's native integrated development environment, and makes many standard development tools available on a macOS system), be sure to accept any extra XCode dependencies during this process. If you are installing onto a system that has Apple Silicon (rather than an Intel CPU) there might be additional steps to configure `$PATH`. The Homebrew installation process will prompt you if this is necessary.

Once installation is complete you can verify that everything works with this command:

```
$ brew doctor
Your system is ready to brew
```

Homebrew is generally a little easier to get along with if you require older versions of PHP, and will usually keep a few minor version releases actively installable. A package definitions for Homebrew is called a *formula*, and these are searchable as follows:
