```
    public function getMaxPassengers(): int
    {
        return $this->maxPassengers;
    }
}

$train = new Train(4);
print "This train can carry {$train->getMaxPassengers()} passengers.\n";

Output:
This train can carry 120 passengers.
```

The parent implementation of `__construct()` is a simple assignment via constructor property promotion. `Train` overloads `__construct()` and requires a calculation: the number of carriages in the train multiplied by the capacity of each carriage. By invoking `parent::__construct()` we're actually calling the `Vehicle` implementation `__construct()`, which sets the `maxPassengers` property for the instantiated object `$train` object. This example is a little contrived, but it serves to demonstrate how to access parent methods. Accessing parent properties works in a similar way:

```
class Vehicle
{
    protected static string $iAm = 'Vehicle';
}

class Car extends Vehicle
{
    protected static string $iAm = 'Car';

    public static function whatAmI(): void
    {
        print "I am a " . self::$iAm . PHP_EOL;
        print "I am also a " . parent::$iAm . PHP_EOL;
    }
}

Car::whatAmI();
```
