(reflection) class that matches the information you have at the time. If we had a class name, we'd use `new ReflectionClass('SomeClass')`, if we have an object, we'd use `new ReflectionObject($object)`. Let's make an object and use `ReflectionObject`…

```
$obj = new Cleric();
$refObj = new ReflectionObject($obj);
```

… and take it for a spin. First up, we'll inspect the properties:

```
print "Class {$refObj->getShortName()} has the following properties..." .
PHP_EOL;
foreach ($refObj->getProperties() as $refProp) {
    $modifiers = Reflection::getModifierNames($refProp->getModifiers());
    $modifiers = implode(' ', $modifiers);
    print "  {$modifiers} {$refProp->getType()->getName()}: ";
    print $refProp->getName() . PHP_EOL;
}
```

```
Output:
Class Cleric has the following properties...
  public int: level
  private int: exp
  protected int: gold
```

As you can see, the `ReflectionObject` instance offers a variety of methods for discovering the public (and private) members, in addition to other information about the class. We've also used the `Reflection::getModifierNames()` static method to transform the bitmasked integer returned by `ReflectionObject::getModifiers()` into human-readable strings.

The following table lists a (non-exhaustive) selection of `ReflectionClass`/`ReflectionObject` methods:
