```
print_r(date_parse_from_format(
    'Y-m-d',
    '2024-09-01 01:02:03 PDT'
));
```

```
Output:
    [year] => 2024
    [month] => 9
    [day] => 1
    [hour] =>
    [minute] =>
    ...
    [error_count] => 1
    [errors] => Array
       (
          [10] => Trailing data
          ...
```

The `error_count` and `errors` elements can obviously form the basis for some error handling.

date_sun_info()

This function takes a Unix timestamp and geoposition data and returns an array of information about daylight hours (sunrise, sunset, twilight hours, and so on). Let's go with one of my favorite landmarks, San Francisco's Coit Tower, which is located at lat. *37.80257289230897*, long. *–122.40579001693803*:

```
print_r(date_sun_info(
    timestamp: 1725364800,
    latitude: 37.80257289230897,
    longitude: -122.40579001693803
));
```

```
Output:
Array
(
    [sunrise] => 1725370847
```
