mathematical operation) and assigns it to a variable identified with the symbol (name) `number`. Note that the statement `1;` is perfectly valid PHP code. The PHP interpreter has parsed it, found no problems, and allowed execution. It doesn't actually do anything, but neither does it emit any errors (there are various tools that will, however, warn about code such as this).

As a final exercise in this section, let's take a more complex statement and identify the syntax structures.

```
$number = 1 + 1;
var_dump(
    $number == 1 + 1
);

Output:
bool(true)
```

The code above contains two statements. The first assigns the result of an operation to the variable `$number`, as per the previous example. The second statement (which spans multiple lines) calls a built-in function `var_dump()`, and passes the result of a logical expression into that function. The syntax can be broken down into tokens (indivisible units) as follows:

Table 1-2. *Syntax tokens*

Token	Type
`1`	Literal value
`+`	Operator (addition)
`=`	Operator (assignment)
`==`	Operator (logical)
`number`	Symbol (variable)
`var_dump`	Symbol (function)
`(`	Beginning function invocation
`)`	End of function invocation
`$`	Variable reference
