```
foreach ($dom->body->childNodes as $child) {
    if ($child->nodeType === XML_TEXT_NODE) {
        var_dump($child->data);
    }

    if ($child->nodeType === XML_ELEMENT_NODE) {
        var_dump($child->tagName);
    }
}

Output:
string(29) "
    Before main element
    "
string(4) "MAIN"
string(27) "
    After main element
```

... and hopefully it now makes sense that the text content of an element itself is treated as a node in the DOM. The full list of `dom` constants can be found at https://www.php.net/manual/en/dom.constants.php – most of them are `nodeType` integers and can be used to identify the type of node a DOM object represents. Some examples are given below:

Table 11-10. *PHP dom extension constants*

`XML_ELEMENT_NODE`	An HTML element
`XML_ATTRIBUTE_NODE`	An element attribute
`XML_TEXT_NODE`	Plain text contained within an element
`XML_HTML_DOCUMENT_NODE`	The full HTML document (node is a `Dom\HTMLDocument` instance)

By matching the `nodeType` property to `XML_ELEMENT_NODE` in our example above, we know that the child element can be treated as an HTML element and that it will have a `tagName` (which is the qualified HTML name of the element – `main` in this case – uppercased).
