Recipe 1: Implementing Server-Side Data Validation

It's great to see you enhancing your app to manage user data reliably. Let us consider the situation wherein your team in recent review meet, discovered that inconsistencies and potential security vulnerabilities could arise without proper validation of user inputs. To make sure your data follows the rules and is formatted correctly, you decided to use strong server-side validation. In our Linux-based Laravel 11 environment managed via PhpStorm and using Laravel Breeze for authentication, it's super important to enforce data validation. Now, we will learn to use Laravel's built-in Validator to enforce server-side data validation rules. This ensures that every incoming request is processed correctly and follows your business logic.

Introducing Laravel's Validator

In practice, data validation is the first line of defense against invalid or malicious inputs. Business rules say that certain fields —like email addresses, passwords, and usernames—have to follow certain formats and rules. For example, you can make sure that user emails are unique and formatted properly, that passwords are at least a certain length, and that names consist only of alphabetic characters.
