Summary

At this point, you've got a solid foundation for developing Laravel on your Linux environment. You installed PHP 8.0 and the essential extensions, set up Composer to manage PHP dependencies, and used it to install Laravel 11 without a hitch. You configured your environment variables, generated the necessary application key, and verified your setup by running the Laravel development server. Then, you learned how to navigate Laravel's directory structure and set the right Linux file permissions for key folders like storage and bootstrap/cache. This made sure everything worked right and was secure. You also set up a solid development environment by installing key tools like PhpStorm, Laravel Debugbar, and Telescope, which upped your coding, debugging, and system monitoring skills. At last, you got Git version control set up for your project, came up with some commit conventions, and hooked your local repository up to remote platforms. That way, your team can work together and keep track of your code more easily. Every step builds on the previous one, getting you ready for more advanced projects without repeating what's already been done.
