The code above is equivalent to the construct `if ($var == 'bar')` / `elseif ($var == 'foo')`, and note the weakly typed comparison: `switch` comparisons are always loosely typed. `switch` constructs provide a little more flexibility than just acting as syntactic sugar for `if`/`elseif`. Take a look at the following:

```
function logicDemo(string $var): void
{
    switch ($var) {
        case 'bar':
            print 'bar ';
        case 'foo':
            print 'foo ';
        case 'qux':
            print 'qux ';
    }
    print PHP_EOL;
}
logicDemo('qux');
logicDemo('foo');
logicDemo('bar');
```

```
Output:
qux
foo qux
bar foo qux
```

This highlights an interesting feature of `switch`: once a `case` is matched, execution continues to "fall through" to the remaining cases, as we can see from the output. This behavior might be desired, but if not, then use the keyword `break` to prevent it:

```
    ...
    switch ($var) {
        case 'bar':
            print 'bar ';
            break;
        case 'foo':
            print 'foo ';
            break;
```
