Installing PHP extensions can be done via the package manager in exactly the same way that PHP itself was installed. Typically you can just combine the extension name with `php-` and search for that:

```
$ apt-cache search php-ldap
php-ldap - LDAP module for PHP [default]
php5.6-ldap - LDAP module for PHP
php7.0-ldap - LDAP module for PHP
...
```

```
$ dnf search php-ldap
Matched fields: name (exact)
 php-ldap.x86_64    A module for PHP applications that use LDAP
Matched fields: name
 php74-php-ldap.x86_64  A module for PHP applications that use LDAP
 php80-php-ldap.x86_64  A module for PHP applications that use LDAP
...
```

Once located, just use the package manager as normal.

Docker

An attractive alternative to trashing your filesystem or living in dependency hell is the hot new thing called Docker (well, maybe not that new anymore but it's still the hotness). Docker is a platform that enables software delivery using *containers*, which is fancy way of saying that software and all its dependencies (including OS and environment) are run in an isolated, virtualized space, a little bit like a *Virtual Machine* (aka a VM, which is a full-fat operating system running through a hypervisor such as VirtualBox or VMWare).

Unlike VMs, Docker containers on Linux are essentially running as just another service. They don't require the overhead of a hypervisor (unless running on a non-Linux system) and they have controlled access to the real hardware of the machine running the container, rather than the simulated hardware of a VM. For non-Linux systems, a single Linux VM is required because Docker depends heavily on Linux kernel features for resource isolation, but the details are abstracted away inside the Docker service so you don't have to think about them.
