- Forward a TCP port on the Docker host system to TCP 80 in the `nginx` container.
- Configure `nginx` to function as a reverse proxy for `.php` resources.
- Shared network so that `php-fpm` container can receive the requests from `nginx`.
- Matching filesystem layouts between the two containers for the target PHP files.

To meet these criteria, our `docker-compose.yaml` looks like this:

```
version: "3"
services:
  nginx:
    build:
      context: .
      dockerfile: ./Dockerfile
    ports:
      - "8080:80"
    networks:
      - internal
    volumes:
      - ./:/var/www/html
  php-fpm:
    image: php:8.4-fpm
    networks:
      - internal
    volumes:
      - ./:/var/www/html
networks:
  internal:
    driver: bridge
```

This yaml file defines a `services` node with two children, `nginx` (which uses the `nginx:1.25` image) and `php-fpm` (which uses the `php:8.4-fpm` image). The `networks.internal` node defines a shared network that both services can use, and is configured with the Docker's `bridge` network driver. `services.nginx` and `services.php-fpm`
