Table 8-15. *Transform by insertion functions*

`chunk_split()`	Insert a separator byte sequence every N bytes
`nl2br()`	Inserts an HTML line break at every newline byte sequence
`number_format()`	Formats a numeric string with grouped thousands and an optional decimal separator

`printf()`
`sprintf()`
`fprintf()`
`vprintf()`
`vfprintf()`
	Interpolate variables into a formatted string

`wordwrap()`	Add a specified byte sequence every N bytes, with additional logic for long words

chunk_split(), wordwrap()

`chunk_split()` is a simple function that simply inserts the ASCII "CRLF" bytes (*0x13* carriage-return and *0x10* line-feed) at set intervals as separator characters. By default, this is every seventy-six bytes; the example below specifies an interval of 4:

```
print chunk_split('A string of text', 4);
```

```
Output:
A st
ring
 of
text
```

If necessary, a third argument can be used to specify the byte sequence used for separation. Splitting strings like this is useful for conforming to internet standards for transmitting various messages (such as email). Note that this function operates at a binary level; it is not aware of character boundaries for multi-byte encoding and will cheerfully break any encoding that is not single-byte.
