```
Output:
object(Dom\NodeList)#7 (1) {
  ["length"]=>
  int(4)
}
```

Our expression is `/child::data/descendant::git/child::project/attribute::*`, which means "from the document node, localize to the immediate child node `data`, then localize to child node(s) `git` at any depth, then to immediate child nodes `project`, then finally to the entire set of attributes for occurrences of the `project` nodes." If we were interested only in a particular attribute name, we would swap the wildcard * for the name, `/attribute::class`, for example, would return all the `class` attributes of all nodes in the context. In our case the result of `...attribute::*` is a node list of length four. Now, our `git` node contains four child `project` elements…

```
...
    <git>
      <project name="javascript">Lovely JS</project>
      <project name="php">Lovely PHP</project>
      <project name="VB6" status="abandoned">Nasty VB6</project>
      <project>EMPTY</project>
    </git>
...
```

… but what exactly did we get back from our query? Did we get four `project` elements? Let's dig into those results:

```
foreach ($results as $node) {
    print get_class($node) . " has value: {$node->value}" . PHP_EOL;
}
```

```
Output:
Dom\Attr has value: javascript
Dom\Attr has value: php
Dom\Attr has value: VB6
Dom\Attr has value: abandoned
```
